

1 Theory

1. CBR methods differs from other machine learning approaches in a few ways. Other machine learning approaches have a training phase and generalizes from the examples given here, in CBR the problem solving is lazy, meaning that it waits until a new case is given before doing any computation. CBR also stores previous cases or data, whereas other machine learning approaches discards the training data as soon as it has been used to update their model.
2. Memory organisation packets (MOPs) is one of the ways cognitive science has influenced CBR. MOPs are dynamic memory models, which represents classes of situations, their typical goals and the participating actors. MOPs are designed to evolve and are interconnected in networks.

In addition to MOPs, there are thematic organisation packets (TOPs). These packets contain general knowledge of the relations between goals and event sequences across contexts.

3. *Surface similarity* is concerned with the surface features of the cases. These features are provided as part of the case's description and is usually represented as attribute-value pairs. The features of the new case is compared with experienced cases and given a similarity value, which is a number between 0 and 1, where 1 is exactly similar and 0 not similar at all. Each of these similarities is weighted based on their importance and combined into a global similarity score. An example of this can be two patients who both present with the same symptoms, or two cases in court where the same crime has been committed.

Structural similarity is used when cases are represented by complex structures, such as graphs or first-order terms. This type of similarity heavily uses domain knowledge. Structural similarity can be used to see how similar two buildings are based on the arrangement of the rooms, which can be represented as a graph structure. Another example is a pipe system which consists of several different parts.

4. Each attribute is compared individually to create a local similarity score, then each local similarity score is combined in some way, such as giving each attribute a weight, to create the global similarity score. This score is used to determine which case is the most similar to this one.
5. Case-based reasoning systems store their knowledge in Knowledge containers. These containers describe how and where knowledge is stored. There are four major knowledge containers: vocabulary, similarity, case base and adaptation. These 4 types of knowledge can combined be used to solve a problem.
 - The vocabulary container determines what can be discussed explicitly. For example, the word heart rate must be known in order to discuss it. This word and its meaning would be stored in the vocabulary container. It is also possible to create sub-containers such as names of employees, companies or products in a supermarket.
 - The similarity container consists of all knowledge needed to determine what makes a case similar to another such that their solutions can be reciprocally reused.
 - The case base container contains experiences as cases. The experiences may be from the past, constructed from existing cases or artificially made.
 - The adaptation container contains knowledge needed to adapt cases to solve new problems. Usually this contains rules that determine how previous solutions can be transformed to fit a new case.

Case Retrieval

e) Three different similarity measures was created for the weight attribute. The first similarity measure gives an exact match a similarity score of 1.0 and then linearly decreases down to 0.0 the further away the weight value is. This similarity measure can be seen in Figure 3.

The next measure decreases linearly until the weight value is $\pm 100kg$ away, here it is given a similarity score of 0.1. Then decreases linearly from this point as well.

The third measure is a smooth step function at $\pm 30kg$. This means that weight values closer than $30kg$ is given a near 1.0 score (with exact match a full 1.0 score), and weight values further than $30kg$ apart a close to 0.0 similarity score.

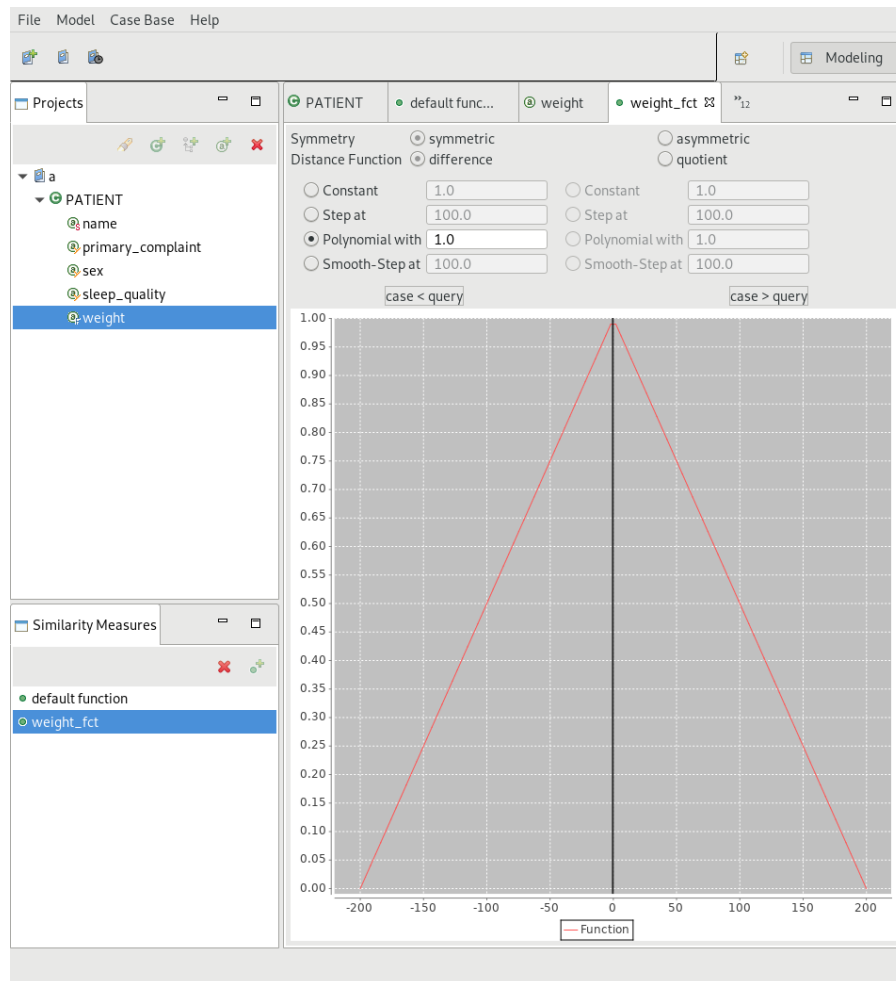

Figure 3: A similarity measure for the weight attribute

The global similarity measure is shown in Figure 4. Here the name and sex attributes are ignored. The weight attribute uses the smooth step function explained previously. The sleep quality function makes high and medium similar, medium and low similar, but high and low is not very similar. Finally, the primary_complaint similarity measure makes symptoms that (I think) are similar score high, such as back pain and joint pain. Symptoms that I consider not similar is given a low score, such as back pain sneezing.

sleep_quali	true	0.7	sleep_fct
weight	true	0.7	weight_smooth_step_fct

Figure 4: The global similarity measure for the patient concept.

- f) In Figure 5a a retrieval query for a complaint of stomach problems, high sleep quality and a weight of 100kg was issued. The top three results for this were Benjamin, Liam, and Isabella, with similarity scores

0.88, 0.58 and 0.48 respectively. Benjamin, the highest scorer, had a complaint of stomach problems, medium sleep quality and weighed 90kg. This scored high because the complaints were similar, and the sleep quality differed little. The weights were also similar.

The next result, Liam, only scored 0.58. His case has primary complaint as joint pain, sleep quality as high and weighs 95kg. This result shows how much the primary complaint affects the similarity scores. Since stomach problems and joint pain does not have much in common he scores poorly, even though his sleep quality and weight matches better than Benjamin.

The third result, Isabella, is 0.48 similar. Isabella's case consists of a stomach problem complaint, low sleep quality and a weight of 60kg. The reason for such a low score is because Isabella is outside the 30kg difference in our weight function, which means her weight score is 0. Her sleep quality is also far from the queried sleep quality, and therefore having the same complaint is the only thing that is similar in these two cases.

(e)

Figure 5: Five retrieval queries.

None of the results are unexpected, Some of the queries resulted in a 1.0 match when the complaint and sleep quality matched and the weight was within a ± 30 range. Other results scored close to zero (0.06 for Olivia in Figure 5e). This is caused by a large gap in their weights, symptoms that are not similar and different sleep quality.

- g) Diagnosing patients is a common problem for doctors, and since the primary complaint attribute already

existed this is the problem I have decided to use for the patient concept. In order to do this I added a diagnosis attribute with type string. Then I gave all instances of patient a diagnosis fitting with their complaint. In the global similarity measure I disabled the diagnosis attribute since it should not be used to determine similarity.

The four steps in the CBR-cycle can be executed in myCBR as follows:

- **Retrieve** is done by executing a retrieval in myCBR with the new problem as query parameters. This gives a list of the most similar cases.
- **Reuse** can be done simply by looking under the top result to see what diagnosis the retrieved patient was given. This diagnosis can then be used for the new patient.
- **Revision** is done manually, after finding a solution, the user of myCBR can revise the solution if necessary.
- **Retain** is done by adding a new instance to the case base with the query parameters and the solution from the retrieve or revise steps.
